Exploratory analysis of RNA-seq dataset

gg

2016-02-01

To run this file: Rscript -e "rmarkdown::render('biplots_filter.Rmd')"

Setup

```
library(compositions)
library(zCompositions)
library(ALDEx2)
# you can get this from:
# https://github.com/DavidRLovell/propr
source("~/git/proprBayes/R/propr-functions.R")

library(igraph)
library(car)

################ incorporating phi into ALDEx
# calculate phi on Dirichlet log-ratio distributions
# returns dataframe of the lower-triangle of symmetrical phi metric
# requires David Lovell's propr.phisym function
#
# THIS IS NOW IN THE proprBayes source
#
############# end functions
```

This will generate biplots with various things painted on top for use as figures, and will serve as a supplement for how the data was processed.

Filter the refseq to a mean count across samples of greater than 5, and remove outlier samples. These are defined as samples that have abberrant taxonomic composition or that have an abberrant phenotype for their taxonomic composition. In essence these are one-off samples. The reasons for filtering are:

Samples 3A, 31S, 13B and 15B are near the midpoint on the right, and 19A and 8B are near the midpoint on the left. Five of these six microbiomes are atypical, and the other 19A is exclusively L. iners, but phenotypically is BV. We next exclude these six samples and re-examine the partitioning.

3A near right midpoint mix of L. iners and BV expression long branch 31S near right midpoint expresses L. crispatus and BV long branch 13B near right midpoint expresses exclusively Megasphaera long branch 15B near right midpoint significant Bifidobacteria long branch 8B near left midpoint mix of L. jensenii and G. vaginalis mid branch 19A near left midpoint L.iners but expresses BV long branch

This is a form biplot that represents distances between samples with variances of components mapped onto the plot.

#####
```

This is a good representation of the data explaining 0.477 proportion of the variance in the data on the first component, and a much smaller amount on the second and later components. This reduced dataset contains 10052 genes. We can see that the samples cluster into a few fairly discrete groups. These groups contain fairly discrete sets of genes, and we can infer that the sample set distributions are driven by gene occurrence in different genomes.

To get around the correlation between gene occurrence and expression, we aggregate the data to the SEED subsystem 4 level. This is done on the same set of samples.

```
